ABSTRACT

The evolution of white dwarfs is essentially a cooling process that depends primarily on the energy stored in their degenerate cores and on the transparency of their envelopes. In this paper we compute accurate cooling sequences for carbon–oxygen white dwarfs with hydrogen dominated atmospheres for the full range of masses of interest. For this purpose we use the most accurate available physical inputs for both the equation of state and opacities of the envelope and for the thermodynamic quantities of the degenerate core. We also investigate the role of the latent heat in the computed cooling sequences. We present separately cooling sequences in which the effects of phase separation of the carbon–oxygen binary mixture upon crystallization have been neglected, and the delay introduced in the cooling times when this mechanism is properly taken into account, in order to compare our results with other published cooling sequences which do not include a treatment of this phenomenon. We find that the cooling ages of very cool white dwarfs with pure hydrogen atmospheres have been systematically underestimated by roughly 1.5 Gyr at $\log(L/L_{\odot}) = -4.5$ for an otherwise typical $\sim 0.6 M_{\odot}$ white dwarf, when phase separation is neglected. If phase separation of the binary mixture is included then the cooling ages are further increased by roughly 10%. Cooling tracks and cooling isochrones in several color–magnitude diagrams are presented as well.

Subject headings: stars: interiors — white dwarfs.

1. INTRODUCTION

White dwarfs are well studied objects and the physical processes that control their evolution are relatively well understood. In fact, most phases of white dwarf evolution can be succesfully characterized as a cooling process. That is, white dwarfs slowly radiate at the expense of the residual thermal energy of their ions. The release of thermal energy lasts for long time scales — of the order of the age of the galactic disk ($\sim$ 10 Gyr). While their detailed energy budget is still today somehow controversial — the reason being basically the release of gravitational energy associated to phase separation upon crystallization (Mochkovitch 1983; García–Berro et al 1988a,b; Isern et al 1997) — their mechanical structures, which are largely supported by the pressure of the gas of degenerate electrons, are very well modeled except for the outer layers. These layers control the energy output and their correct modeling is necessary to properly understand the evolution of white dwarfs. This is especially true at very low luminosities when most of the white dwarf interior has already crystallized and the cooling process is controlled almost exclusively by the behavior of the very outer layers. The situation was quite unsatisfactory until very recently, when new developements in the physics of white dwarf atmospheres allowed the calculation of reliable hydrogen–dominated white dwarf atmospheres down to effective temperatures as low as 1500 K (Saumon & Jacobson 1999; Hansen 1999).

The study of very cool white dwarfs bears important consequences, since the recent results of the microlensing experiments carried out by the MACHO team (Alcock et al 1997) yield that perhaps a substantial fraction of the halo dark matter could be in the form of very cool white dwarfs. The search for this elusive white dwarfs has not been successful yet, although there are evidences that perhaps the observational counterparts of these white dwarfs could be the stellar objects recently reported in the Hubble Deep Field (Ibata et al 1999; Méndez & Minniti 1999). Most probably one of the reasons for this failure in detecting very cool white dwarfs was that their colors were expected to be redder than they really are (Hansen 1999). Moreover, the luminosity function of disk white dwarfs has been repeatedly used during the last decade to provide independent estimates of the age of galactic disk (Winget et al 1987; García–Berro et al 1988b; Hernanz et al 1994).

In view of the recent progresses in the physics of the dense hydrogen plasma we compute new cooling sequences which will be invaluable for the study of the structure and age of our Galaxy and its halo. The paper is organized as follows: in §2 we briefly describe the evolutionary code and the adopted physical inputs, in §3 we discuss in detail the cooling sequences, we compare them to other cooling sequences available so far, and we show their evolution in the color–magnitude diagram. Finally, our conclusions are drawn in §4.

2. THE EVOLUTIONARY CODE

The adopted cooling code is the same evolutionary code used by Salaris et al (1997) in which we have included an accurate treatment of the crystallization process of the carbon–oxygen (C/O) core, together with updated input physics suitable for computing white dwarf evolution,

which will be described in the following paragraphs. Thus the cooling sequences described in the next section have been computed using a full evolutionary code instead of the approximate procedure used, for instance, in García–Berro et al (1996).

The equation of state (EOS) for the C/O binary mixture in the gaseous phase was taken from Straniero (1988), while for the liquid and solid phases the detailed EOS from Segretain et al (1994) was used. As for the pure H and He regions, we used the results of Saumon, Chabrier & Van Horn (1995), supplemented at the highest densities by an EOS for H and He using the physical prescriptions by Segretain et al (1994). Crystallization was considered to occur at $\Gamma = 180$, where Γ is the usual plasma ion coupling parameter. The associated release of latent heat was assumed to be equal to 0.77 $k_{\rm B}T$ per ion (see sections 3.1 and 3.2 below). The additional energy release due to phase separation of the C/O mixture upon crystallization was computed following closely Isern et al (1997, 2000).

Neutrino energy losses were taken from Itoh et al (1996). The conductive opacities for the liquid and solid phase of Itoh et al (1983) and Mitake, Ichimaru & Itoh (1984) were adopted; for the range of temperatures and densities not covered by the previous results, we used the conductivities by Hubbard & Lampe (1969). OPAL radiative opacities (Iglesias & Rogers 1993) with $Z = 0$ were used for $T \geq 6000$ K in the He and H envelopes. In the H envelope, and for the temperatures and densities not covered by the OPAL tables, we computed Rosseland mean opacities from the monochromatic opacities of Saumon & Jacobson (1999), after adding the contribution of hydrogen lines. The surface boundary conditions needed to integrate the stellar structure (P and T at $\tau = 200$, where the diffusion approximation is valid and one can safely start to integrate the full set of stellar structure equations using Rosseland mean opacities) were obtained from detailed non–grey model atmospheres: for $T_{\rm eff} \leq 4000$ K we used the results of Saumon & Jacobson (1999), whereas for higher temperatures, the results of Bergeron, Wesemael & Beauchamp (1995) were adopted. Bolometric luminosities and effective temperatures of the white dwarf models were transformed into V magnitudes and colors by using the bolometric corrections and color–$T_{\rm eff}$ relations derived from the same model atmospheres. Superadiabatic convection in the envelope was treated according to the ML2 parametrization of the mixing length theory (see Bergeron, Wesemael & Fontaine 1992, and references therein), which is the same formalism used also in the Saumon & Jacobson (1999) and Bergeron, Wesemael & Beauchamp (1995) computations.

When computing the cooling sequences, for each white dwarf mass an initial model was converged at $\log(L/L_{\odot}) \approx 2.0$ by considering a C/O core with the chemical composition profile taken from the evolutionary pre–white dwarf computations of Salaris et al (1997), together with "thick" H and He layers ($M_{\rm H} = 10^{-4} M_{\rm WD}$, $M_{\rm He} = 10^{-2} M_{\rm WD}$), and it was evolved down to luminosities $\log(L/L_{\odot}) \approx -5.5$, when all the model sequences already have large enough ages.

3. THE COOLING SEQUENCES

We have computed cooling sequences neglecting and including the release of gravitational energy associated to phase separation with the above described physical inputs for white dwarf masses $M_{\rm WD} = 0.538$, 0.551, 0.606, 0.682, 0.768, 0.867 and 1.0 $M_{\odot}$, which are the core masses derived in Salaris et al (1997). The cooling sequences for a typical 0.606 $M_{\odot}$ white dwarf for both cases are shown in figure 1. The adopted release of latent heat for the calculations shown in figure 1 is $k_{\rm B}T$ per ion in order to facilitate the comparison with similar calculations. The solid line corresponds to the case in which the release of gravitational energy due to phase separation has been neglected, whereas the dotted line corresponds to the case in which the effects of phase separation have been fully taken into account. Also shown in figure 1 are the cooling sequences computed with $l = 0.77\ k_{\rm B}T$ per ion for the two above mentioned cases in which phase separation has been included or neglected (long dashed line and dashed dotted line, respectively).

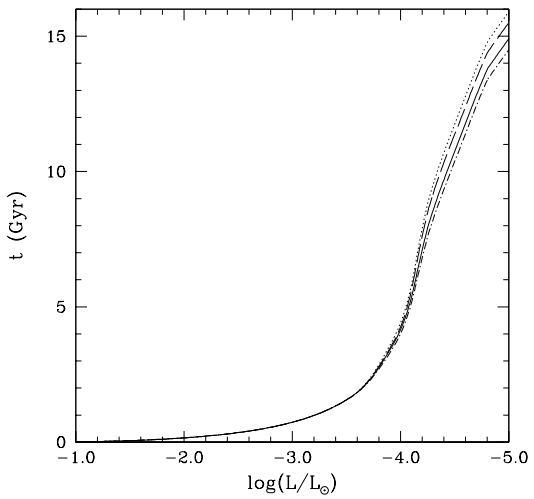

FIG. 1.— Cooling sequences for a 0.606 $M_{\odot}$ white dwarf neglecting phase separation (solid line) and taking into account phase separation (dotted line) computed assuming $l = k_{\rm B}T$ per particle. Also shown are the the cooling sequences obtained with $l = 0.77\ k_{\rm B}T$ per particle in both cases (dashed dotted line and long dashed line, respectively).

3.1. *Comparison with previous evolutionary calculations*

The most distinctive feature of the cooling sequences presented here is the duration of the cooling phase itself, which is larger than in other equivalent calculations (Hansen 1999, Althaus & Benvenuto 1998). For instance, for the case in which the effects of phase separation have been neglected and the adopted latent heat is $k_{\rm B}T$ per particle, at $\log(L/L_{\odot}) = -4.5$ the calculations for the 0.606 $M_{\odot}$ white dwarf reported here yield a cooling age of $t \simeq 10.7$ Gyr, in contrast with the calculation of Hansen (1999) which, for the same core mass, the same adopted latent heat and the same adopted envelope, yields $t \simeq 8.9$ Gyr. That is, the cooling age of a 0.606 $M_{\odot}$ white dwarf derived in the present work at this luminosity is $\sim$20% larger than the cooling age derived by Hansen (1999).

This difference can be easily accounted for from a detailed analysis of figure 2, where the core temperature–luminosity ($T_{\rm c} - L$) relationship obtained in this work — solid line — and in Hansen (1999) — dotted line — are shown in the upper panel, whereas in the lower panel their

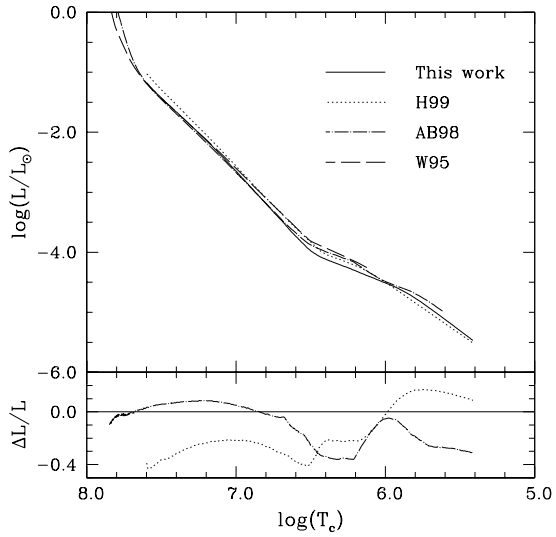

FIG. 2.— $T_{\rm c} - L$ relationship for the three cooling sequences of a $\sim 0.6\ M_{\odot}$ white dwarf discussed in this paper (upper panel). The solid line corresponds to the relationship derived in this work, the dotted line is the relationship derived by Hansen (1999), and the dashed–dotted line is that of Althaus & Benvenuto (1998). In the lower panel the relative differences of the latter cooling sequences with our model are shown. For the sake of completeness we also show the $T_{\rm c} - L$ relationship obtained by Wood (1995) as a long dashed line.

relative difference is shown as a function of the core temperature. As it can be seen there, for a given $T_{\rm c}$ the luminosity is about 30% larger down to $\log(L/L_{\odot}) \simeq -4.5$ and, thus, the model envelopes of Hansen (1999) are systematically more transparent than our envelopes for the same $T_{\rm c}$, resulting in a more efficient cooling of the white dwarf interior. To be precise, let us quantify how this affects the cooling sequences. For luminosities smaller than $L_0 = 10^{-2} L_{\odot}$ the contribution of thermal neutrinos and nuclear reactions are negligible and, thus, one can safely assume that the sole contribution to the cooling process is the release of binding energy. Therefore we can write:

$$L = -\frac{dB}{dt}. \qquad (1)$$

Accordingly, the difference in the cooling times between both cooling sequences can be easily estimated:

$$\Delta t(L) = \int_{L_0}^{L(T_{\rm c})} \Big(\frac{1}{L_{\rm BH}} - \frac{1}{L_{\rm TW}} \Big) \frac{dB}{dT_{\rm c}} dT_{\rm c} \qquad (2)$$

where $L_{\rm TW}(T_{\rm c})$ stands for the $T_{\rm c} - L$ relationship derived in this paper and $L_{\rm BH}(T_{\rm c})$ is the one derived by Hansen (1999). We have independently computed a set of binding energies with the same equation of state described in the previous section and used equation (2) to obtain an estimate of the difference introduced by the differences in the transparency of the envelope. At $\log(L/L_{\odot}) = -4.5$ we got $\Delta t \simeq 2.1$ Gyr, which is in good agreement with the value derived from the evolutionary code (1.8 Gyr). Thus, this difference can be mainly ascribed to the differences in the transparency of the adopted model envelopes.

Now the question is, why is there a difference in the model envelopes? This question cannot be answered categorically. In fact, we are using the same thicknesses for the H and He layers, the same envelope EOS and the same OPAL ($Z = 0$) opacities for $T \geq 6000$ K, but not the same model atmospheres for the boundary conditions. However we do have indirect ways of checking the consistency of our results.

We recomputed the cooling sequence of our $0.606\ M_{\odot}$ white dwarf using a grey $T(\tau)$ relation for deriving the boundary conditions. We found that the $T_{\rm c} - L$ relationship derived in this way was coincident, as long as $T_{\rm eff} \geq 6000$ K, with the one obtained using the model atmospheres boundary conditions, in agreement with the findings by Hansen (1999). This allows us to directly compare our $T_{\rm c} - L$ relationship (for $T_{\rm eff} \geq 6000$ K) with the independent results of Althaus & Benvenuto (1998) for their $0.600\ M_{\odot}$ white dwarf cooling track. This calculation adopts our same metallicity and thickness for the He and H layers. Moreover, Althaus & Benvenuto (1998) also used the same EOS in the envelope and the same OPAL opacities for $T \geq 6000$ K. The only differences of this calculation with respect to our calculation and that of Hansen (1999) are threefold. First, Althaus & Benvenuto (1998) used a grey $T(\tau)$ relation for deriving the boundary conditions. As we have shown, this procedure is well justified as long as $T_{\rm eff} \geq 6000$ K. Second, Althaus & Benvenuto (1998) adopted a slightly different C/O profile for the core. Since the adopted internal C/O stratification does not affect at all the derived $T_{\rm c} - L$ relationship, the slightly different C/O profile adopted by Althaus & Benvenuto (1998) does not influence the result of the comparison. Third, they employed the full–spectrum turbulence theory of convection by Canuto, Goldman & Mazzitelli (1996) instead of the mixing length theory, for the computation of the convective superadiabatic gradient in the envelope. However, the treatment of superadiabatic convection does not affect the $T_{\rm c} - L$ relationship.

In the upper panel of figure 2 we also show the core temperature–luminosity relationship derived by Althaus & Benvenuto (1998) as a dashed–dotted line, whereas in the lower panel of this figure the relative difference with respect to the present calculation is shown. Our result closely follows that of Althaus & Benvenuto (1998) in the core temperature range when $T_{\rm eff} \geq 6000$ K, and therefore it is quite apparent from this figure that for some reason the model envelopes of Hansen (1999) appear to be, at least in this temperature range, far more transparent than ours. It is however remarkable that the calculation reported in the present work and that of Hansen (1999) are parallel for almost the full range of luminosities studied here. Finally both our calculation and that of Hansen (1999) differ considerably at low $T_{\rm c}$ from the calculation of Althaus & Benvenuto (1998), as is expected because of the improved atmospheric treatment at very low luminosities. For the sake of completeness we also show the relationship obtained by Wood (1995) as a long dashed line (he also used a grey $T(\tau)$ relationship to derive the boundary conditions), although we refrain from doing a detailed comparison with our results because this cooling sequence was computed using a different EOS for the white dwarf envelope. Note, however, that at high central temperatures, where different treatments of non-ideal effects should not substantially affect the envelope EOS, the $T_{\rm c} - L$ relationship of Wood (1995) is in good agreement with our results.

The ultimate reasons for the differences found in the $T_{\rm c}-L$ relationship (and cooling times) with respect to Hansen (1999) results could be various. First, it may have to do, at least for $T_{\rm eff} \leq 6000$ K (which roughly corresponds to $\log(L/L_{\odot}) = -3.7$ and $\log(T_{\rm c}) = 6.6$ for our models) with the low temperature Rosseland mean opacities used for integrating the stellar structure equations, which are not the same in both calculations.

A contribution can arise also from the treatment of the boundary condition — see the discussion in §2.1 of Hansen (1998). We have compared the values of T and P at τ=2/3 for $\log(g) = 8$ using figure 3 of Hansen (1999), and we have found that for a given effective temperature the values of the pressure used by Hansen (1999) are systematically higher than ours when $T_{\rm eff}$ is lower than 5500 K. The maximum difference (in $\log P$) is ~ 0.62 at $T_{\rm eff} = 4000$ K (which roughly correponds to $\log(L/L_{\odot}) = -4.5$) and steadily decreases to ~ 0.41 at $T_{\rm eff} = 3000$ K and ~ 0.18 at $T_{\rm eff} = 2000$ K. This means that the model atmospheres of Hansen (1998, 1999) are more transparent than ours. More transparent atmospheres means faster cooling which may explain the difference. We have thus performed a numerical experiment to test the influence of varying the boundary conditions. In the hypothesis that the mentioned differences of pressure at τ=2/3 exist also at higher values of the optical depth, we have modified accordingly our boundary conditions and repeated the computation of the $\sim 0.61\ M_{\odot}$ white dwarf (whose surface gravity is $\log(g) = 8$). We have found that the cooling times at luminosities lower than $\log(L/L_{\odot}) \sim -4.4$ are significantly shorter (up to ~ 1.5 Gyr). However, at luminosities lower than about $\log(L/L_{\odot}) = -4.5$ Hansen (1999) $T_{\rm c} - L$ relationship crosses ours, and at a fixed $T_{\rm c}$ the difference in luminosity is only of about 10% with respect to our results (our luminosities being higher in this case). This shows that the combination of different Rosseland mean opacities and different boundary conditions have a compensating effect, producing a $T_{\rm c} - L$ relationship similar to ours for very dim white dwarfs.

Finally, we have investigated yet another possible source of the difference between the models of Hansen (1999) and our models, that is the treatment of the conductive opacity in the H and He envelope. Although we both use for the conductive opacities in the liquid phase a combination of the Itoh et al (1983) and Hubbard & Lampe (1969) results, we have found that our respective treatments are slightly different (Hansen, private communication; see also Hansen & Phinney 1998). More in detail, we use Itoh et al (1983) conductive opacities for the liquid phase whenever $2 \leq \Gamma \leq \Gamma_{\rm crist}$ and $0.0001 \leq r_{\rm s} \leq 0.5$, where $r_{\rm s}$ is defined as in Itoh et al (1983). Additionally, for the parameter y defined in Itoh et al (1983) we relax the constraint $y < 0.1$ discussed by the authors, following the recommendations by Itoh (1994). At lower densities, Hubbard & Lampe (1969) tables are used. The first two conditions yield a lower limit for the density which depends on the temperature. Instead, in the models of Hansen (1999), when this limit is lower than $\log(\rho) \leq 2$, the tables of Hubbard & Lampe (1969) are used starting from $\log(\rho) = 2$. As an example, for typical values of $\log P$ and $\log T$ at the base of the convective envelope for $\log(L/L_{\odot}) \approx -4.5$ we are employing the results of Itoh et al (1983) whereas in Hansen (1998, 1999) the results of Hubbard & Lampe (1969) were used. However, in the region with $\rho \leq 10^2$ g cm^{-3}, where we are still using the Itoh et al (1983) opacities, the Hubbard & Lampe (1969) opacities are different by at most $\sim 20\%$, which does not influence appreciably the evolution of the white dwarf.

3.2. *The role of the latent heat*

One of the most important sources of energy during the evolution of cooling white dwarfs is the release of latent heat upon crystallization. In fact this source of energy, together with the energy released by chemical fractionation, completely dominates the evolution at relatively low luminosities during a considerable fraction of time. The exact value of the latent heat is obtained from the thermodynamic properties of the plasma during the phase transition. In fact, both the temperature of solidification and the precise value of the latent heat are obtained from the following set of equations:

$$\begin{aligned} P_{\rm L}(\rho, T) &= P_{\rm S}(\rho, T) \\ \mu_{\rm L}(\rho, T) &= \mu_{\rm S}(\rho, T) \end{aligned} \tag{3}$$

where T is the crystallization temperature, P is the pressure, μ is the chemical potential, and the subscripts S and L stand for the solid and the liquid phase, respectively. The phase transition is solved by providing the density in the liquid phase and solving equation (3) for the crystallization temperature and for the density in the solid phase. As a consequence, the solid usually has a different density and the latent heat is then the difference in entropy between both phases. It has been generally assumed that the latent heat is of the order of $k_{\rm B}T$ per particle but, as first pointed out by Lamb & Van Horn (1975), the latent heat can differ by up to 25% from this fiducial value, the exact value depending on the density and temperature of the crystallizing layer.

Since most of the computed cooling sequences adopt this fiducial value, in the previous subsection we have used $k_{\rm B}T$ per particle when comparing our models with previously published results. It is however important to realize that the latent heat depends critically on the adopted equation of state in both the liquid and solid phase. Therefore, in order to be consistent, one should compute the release of latent heat using equation (3) and *the same prescriptions* adopted for the thermodynamic quantities used to describe both phases. Moreover, this fiducial value was derived by Lamb & Van Horn (1975) using the best available physical inputs at that time. Since then, there have been several revisions of the equation of state of very dense plasmas, being the most significant ones those of Stringfellow, De Witt & Slattery (1990) and Iyetomi, Ogata & Ichimaru (1993). We have solved equation (3) using the chemical potential and pressures given by Stringfellow et al (1990) and Iyetomi et al (1993) and we have obtained for the range of densities and temperatures relevant for white dwarf cooling an almost constant value of $l = 0.77\ k_{\rm B}T$ per particle in both cases, which is considerably smaller than the fiducial value adopted in most calculations. This is thus the value we adopt for the cooling sequences described below. The net result is, obviously, a decrease in the cooling times

TABLE 1

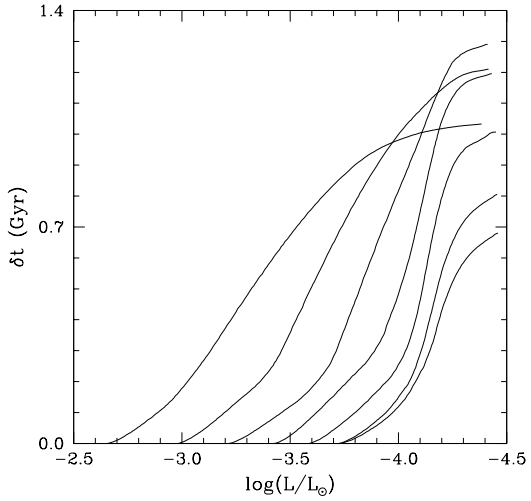

FIG. 3.— Computed delays due to the C/O phase separation for the white dwarf core masses discussed in the text. From right to left: $M_{\rm WD} = 0.538$, 0.551, 0.606, 0.682, 0.768, 0.867 and 1.0 $M_\odot$.

(see figure 1) which for a $\sim 0.61\ M_\odot$ white dwarf is almost 0.4 Gyr at $\log(L/L_\odot) = -4.5$.

3.3. *The effects of phase separation*

Now we turn our attention to the effect of phase separation upon crystallization of the C/O binary mixture. As already noted in Isern et al (2000), this effect is differential. That is, it depends crucially not only on the total amount of gravitational energy released by phase separation upon crystallization but also on the transparency of the envelope. The delay introduced by phase separation at $\log(L/L_\odot) = -4.5$ for our $\sim 0.6\ M_\odot$ model is ~ 1 Gyr. Thus the differential effect of phase separation amounts to 9.6%, in good agreement with the results of Isern et al (2000).

For the sake of completeness, in figure 3 the delays introduced by phase separation upon crystallization are shown for the full range of masses. None of the delays is larger than 1.4 Gyr at $\log(L/L_\odot) = -4.5$, where the crystallization process is complete for all but the lightest white dwarfs. It should be noted as well that, for a fixed $T_{\rm c} - L$ relationship, the delays depend on the profile of the C/O binary mixture, which varies considerably from one core mass to another, and which is extremely dependent on the adopted cross section for the $^{12}{\rm C}(\alpha,\gamma)^{16}{\rm O}$ reaction and on the criterion for convective instability (Salaris et al 1997) used in the pre–white dwarf evolutionary phase. The results of Salaris et al (1997) indicate that the lowest central chemical abundance of ^{16}O occurs for a 1.0 $M_\odot$ white dwarf, thus enhancing the effect of phase separation. Moreover, the size of the central oxygen–rich region reaches its maximum for this mass; this increases the size of the mixing region and, consequently also increases the effect of phase separation. Exactly the opposite occurs for a 0.538 $M_\odot$ white dwarf. For intermediate core masses the situation is more complex since the two previously mentioned effects are not linear and, therefore, the analysis of their combination is more subtle, leading, in any case, to the distribution of delays shown in figure 3. However, it is important to realize that the delay is maximum for the central range of white dwarf core masses (around ~ 0.768 $M_\odot$). In table 1 a summary of the cooling ages for all the white dwarf masses when phase separation is neglected can be found[1] (upper section), together with the accumulated time delays introduced by chemical fractionation at crystallization (bottom section).

Finally, in table 2 we show the total gravitational energy released by phase separation during the crystallization process and we compare it with the total release of latent heat. For the four cooling sequences correspond-

[1]Detailed cooling sequences are available upon request to the authors.

ing to the low mass regime ($M_{\rm WD} \sim 0.54,\ 0.55,\ 0.61$ and $0.68\ M_{\odot}$), the release of gravitational energy (which depends mostly on the adopted phase diagram for the C/O binary mixture and on the pre–white dwarf chemical profile of the C/O mixture) is smaller than the total release of latent heat — but it is of the same order of magnitude — being almost identical for $M_{\rm WD} \sim 0.77\ M_{\odot}$ white dwarf. On the contrary, for the more massive white dwarfs (cooling sequences with masses $M_{\rm WD} \sim 0.87$ and $1.0\ M_{\odot}$) the total release of latent heat is smaller than the release of gravitational energy. Consequently, we stress that this additional source of energy cannot be neglected whatsoever in a realistic calculation.

At this point it should be recalled that the pre–white dwarf stratification of the C/O binary mixture plays a crucial role in determining the delays. If a high effective rate of the $^{12}{\rm C}(\alpha,\gamma)^{16}{\rm O}$ reaction is adopted — as was done in Salaris et al (1997) — the abundance of oxygen in the central layers is as high as 0.74 by mass for a typical $0.606\ M_{\odot}$ white dwarf and the degree of mixing in the liquid layers is strongly reduced by the very steep gradients of chemical composition, thus minimizing the effect of phase separation. However, the effective cross section of the $^{12}{\rm C}(\alpha,\gamma)^{16}{\rm O}$ reaction rate is the subject of active debate and, consequently, the delays shown in figure 3 should be regarded as a conservative lower limit.

3.4. *The colors of very cool DA white dwarfs*

In figure 4 the color–magnitude diagrams for a $0.606\ M_{\odot}$ white dwarf are shown for four standard colors. Starting from the upper left corner and continuing clockwise the following color indices are shown: $V-I$, $J-K$, $V-R$ and $B-V$. The solid line corresponds to a $0.606\ M_{\odot}$ white dwarf and the dashed–dotted line corresponds to a $1.0\ M_{\odot}$ white dwarf. Selected evolutionary stages for $\log t = 7.0$, 8.0, 9.0, 9.5, 10.0 and 10.2 are represented as dots. Both evolutionary tracks are for the case in which phase separation has been neglected. As it can be seen in this figure the first three color indices show a pronounced turn–off at low luminosities, whereas the $B-V$ color index does not. In the infrared colors, intrinsically faint white dwarfs with hydrogen–dominated atmospheres should be bluer than previously thought, as first discussed by Hansen (1998) and Saumon & Jacoboson (1999). This behavior is due to the blocking effect in the infrared of the H_2 collision–induced absorption.

Table 2

Total gravitational energy released by chemical fractionation upon crystallization ($E_{\rm g}$) compared to the total latent heat release ($E_{\rm l}$), both in ergs.

$M/M_{\odot}$	$E_{\rm l}$	$E_{\rm g}$
0.54	1.22×10^{46}	6.27×10^{45}
0.55	1.26×10^{46}	7.65×10^{45}
0.61	1.52×10^{46}	1.11×10^{46}
0.68	1.92×10^{46}	1.66×10^{46}
0.77	2.49×10^{46}	2.44×10^{46}
0.87	3.34×10^{46}	3.98×10^{46}
1.00	4.90×10^{46}	7.37×10^{46}

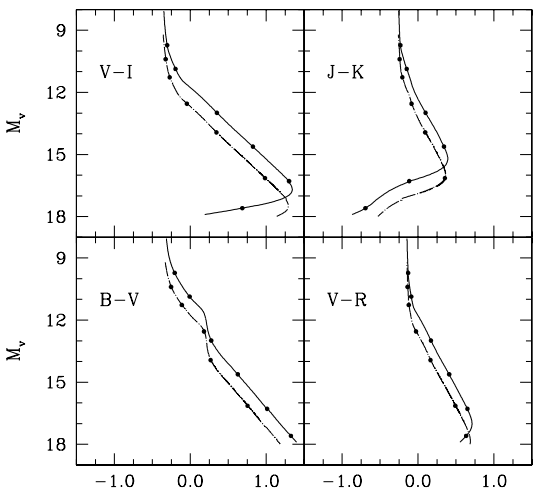

Fig. 4.— Evolution of a $0.606\ M_{\odot}$ white dwarf — solid line — and a $1.0\ M_{\odot}$ white dwarf — dashed–dotted line — in several color–magnitude diagrams. See text for details.

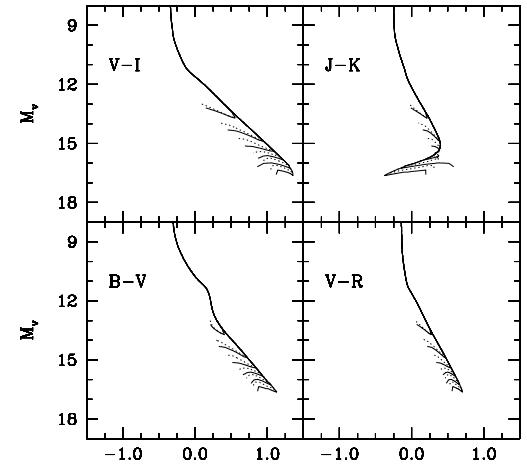

Fig. 5.— Isochrones for the same color–magnitude diagrams of figure 4. See text for details.

Finally, in figure 5 we show white dwarf isochrones for $t = 2$, 4, 6, 8, 10 and 12 Gyr. They are particularly useful when studying the white dwarf populations in stellar clusters, for which the progenitors can be assumed to be coeval and with the same initial chemical composition. Solid lines correspond to the case in which phase separation has been neglected, whereas the dotted lines correspond to the case in which chemical fractionation upon crystallization has been fully taken into account. The calculation of isochrones involves two factors in addition to the cooling sequences. First and most important is the initial–final mass relation, second is the lifetime (up to the thermally pulsing phase) of the white dwarf progenitors. For both, we have adopted the results of Salaris et al (1997) for solar metallicity progenitors. The isochrones were thus computed self–consistently because the same evolutionary code was used for deriving all the required evolutionary data.

We would like to stress that, since the initial–final mass relationship is almost flat in the low mass regime and the mass–main sequence lifetime relationship is very steep, any attempt to derive ages of individual field white dwarfs from the position of low mass white dwarfs in the color–magnitude diagram is subject to potentially large uncertainties, since any small error in the determination of the white dwarf mass translates into a huge relative error on its total age. It should also be pointed out that there is a very common tendency to associate bright white dwarfs with young stars, which is inaccurate since they can be either bright massive white dwarfs — and, indeed, in this case their total age is small — or bright low mass white dwarfs with a low mass progenitor, which has a large main sequence lifetime, and therefore the reverse is true (Díaz–Pinto et al 1994, Isern et al 1999).

As it can be seen in figure 5, in all the color–magnitude diagrams the isochrones show a pronounced turn-off at their dimmer end which, as the age of the isochrone increases, it is located at increasingly larger magnitudes. The presence of this turn–off is due to the contribution of the most massive white dwarfs, while the upper portion of the isochrones closely resembles the cooling track of a $\sim 0.54\ M_{\odot}$ object. The shape of the turn-off is modulated, in the $J-K$ colours (for ages larger than $t = 7-8$ Gyr), by the intrinsic turn to the blue of the individual cooling tracks clearly seen in figure 4. For the $V-I$ and $V-R$ colors the turn to the blue of the individual cooling sequences begins to contribute significantly to the isochrones for ages $t = 13-14$ Gyr.

4. CONCLUSIONS

In this work we have computed the cooling sequences of very cool DA white dwarfs with C/O cores. These cooling sequences include the most accurate physical description of the thermodynamic quantities for both the core and the envelope and have been computed with a well tested, self–consistent evolutionary code. We have computed as well the release of latent heat using the most up to date physical inputs for the liquid–solid phase transition and we have found that for the most recent equations of state of the degenerate core the release of latent heat amounts to $\sim 0.8 k_{\rm B}T$ per particle. Additionally, the release of gravitational energy associated to phase separation during crystallization has been also properly taken into account. Color indices for several bandpasses have also been computed from the most recent synthetic spectra. Our major findings can be summarized as follows. Firstly, we have found that the most recent cooling sequences of Hansen (1999) considerably underestimate the cooling age of C/O white dwarfs with hydrogen dominated atmospheres even when chemical fractionation is neglected. We have traced back the possible source of discrepancy and we have found that at a given core temperature the $T_{\rm c}-L$ relationship of Hansen (1999) differs by roughly 30% with respect to other evolutionary calculations computed with the same physical inputs. This is true not only when the comparison is done with the cooling sequences reported here but also with the cooling sequences by other authors (namely Althaus & Benvenuto 1998). The ultimate reason for this discrepancy remains unidentified although we have explored several possible causes without much success. Secondly, we have also found that a conservative lower limit to the accumulated time delay introduced by the release of gravitational energy associated to phase separation is roughly 10% at $\log(L/L_{\odot}) = -4.5$, in good agreement with the results of Isern et al (2000).

We have transformed our cooling sequences from the $\log(L/L_{\odot})$-$\log(T_{\rm eff})$ plane into various color–magnitude diagrams, and found that intrinsically faint DA white dwarfs have a pronounced turn–off in the infrared colors, and therefore are bluer than previously thought, in good agreement with the results of Hansen (1998, 1999). Cooling isochrones taking into account the evolutionary time of the white dwarf progenitors — suitable for the analysis of white dwarfs in stellar clusters — have been produced as well. They show in all colors a turn–off at the fainter end, due to the contribution of the more massive objects; this turn–off is modulated by the intrinsic turn to the blue of the individual cooling tracks.

Finally we would like to stress the importance of having reliable models of the evolution of white dwarfs and, thus, given the substantial differences in the inferred ages found by different authors, and the complexity of the evolutionary codes needed to compute realistic cooling sequences, more independent calculations are highly desirable.

Acknowledgements This work has been supported by the DGES grants PB97–0983–C03–02 and PB97–0983–C03–03, by the NSF grant AST 97–31438 and by the CIRIT. We sincerely thank our referee, B. Hansen, for very valuable comments and criticism which have considerably improved the original manuscript. We also want to thank P. Bergeron for kindly providing us with model atmospheres. One of us, EGB, also acknowledges the support received from Sun MicroSystems under the Academic Equipment Grant AEG–7824–990325–SP.
